Abstract

In captivity, oogenesis and ovarian follicle maturation in European eel can be induced experimentally using hormonal therapy. The follicle's ability to respond effectively to the induction of maturation and ovulation, resulting in viable eggs, depends on the oocyte stage at the time of induction. We hypothesized that variation in the expression of key hormone receptors in the ovary and size of oocyte lipid droplets are associated with changes in oocyte stage. Thus, we induced ovarian follicle maturation using a priming dose of fish pituitary extract followed by an administration of 17α, 20β-dihydroxy-4-pregnen-3-one (DHP). Females were then strip-spawned, the eggs were fertilized *in vitro*, incubated and larval survival was recorded at 3 days post hatch (dph). The expression of gonadotropin receptors (*fshr*, *lhcgr1* and *lhcgr2*) and estrogen receptors (*esr1*, *esr2a*, *esr2b*, *gpera* and *gperb*) was quantified and the size of oocyte lipid droplets measured. Larval survival at 3 dph was used to differentiate high- and low-quality egg batches. Results showed significantly higher abundance of *lhcgr1* and *esr2a* at priming for high-quality egg batches whereas *fshr* and *gperb* transcripts were significantly higher at DHP injection for low-quality egg batches. Therefore, high levels of *lhcgr1* and *esr2a* may be important for attaining follicular maturational competence, while high *fshr* and *gperb* mRNA levels may indicate inadequate maturational competence. Furthermore, lipid droplet size at DHP and in ovulated eggs was significantly smaller in high-quality egg batches than in low-quality, which indicates that droplet size may be a useful marker of follicular maturational stage.

Key words: estrogen receptors, gonadotropin receptors, lipid droplet, follicular maturation, egg quality

1. Introduction

The oceanic, reproductive stages of European eel (*Anguilla anguilla*) remain undiscovered and sexual maturation neither occurs naturally in their continental habitats nor in captivity. This arrested development results from a strong dopaminergic inhibition (Dufour et al., 1988; Vidal et al., 2004) and a deficient pituitary gonadotropic function, i.e. both gonadotropin synthesis and release are low (Dufour et al., 1983). Experimentally, gonadal development can be induced using hormonal treatments based on fish pituitary extracts in females and human chorionic gonadotropin in males (Fontaine et al. 1964; Yamamoto and Yamauchi, 1974; Dufour et al., 1989; Ohta et al., 1996; Pedersen, 2003). In females, such treatment leads to oocyte growth until maturation. Induction of follicular maturation and ovulation generally requires an additional dose of pituitary extract and an injection of a maturation-inducing steroid (MIS) (Yamauchi, 1990; Ohta et al., 1996; Pedersen, 2003) such as 17α, 20β-dihydroxy-4-pregnen-3-one (DHP) in the case of the eel. Recent advances in eel assisted reproductive technology have enabled the production of viable eggs and yolk-sac larvae (Butts et al., 2016; Sørensen et al., 2016). However, resulting egg quality is variable and low fertilization rate and poor larval survival are often observed. Variation in egg quality is partly related to the timing induction of ovarian follicle maturation and ovulation, as previous studies have shown that hormonal treatment given too early or too late in the reproductive cycle can be ineffective or inefficient (Palstra et al. 2005; Mylonas et al., 2010; Unuma et al., 2011). Because hormones need to bind to receptors to exert their biological function, differences in responsiveness to hormonal treatment could be due to differences in hormone receptor expression.

In teleost fishes, as in other vertebrates, the two pituitary gonadotropin hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH) play major roles in the regulation of oogenesis and

production of sex steroids (Pierce and Parsons, 1981). Gonadotropic function is mediated by specific membrane receptors, the FSH receptor (FSHR) and the LH receptor (LHCGR), which corresponds to the human LHCGR. These are mainly expressed in the somatic cells of the gonads (Rosenfeld et al., 2007), though they can also be expressed in germ cells (Chauvigné et al., 2014). Until recently, it was accepted that teleosts had a single FSHR and a single LHCGR encoded by *fshr* and *lhcgr* genes, respectively. However, in addition to *fshr*, Maugars and Dufour (2015) identified and characterized two *lhcgr* genes (*lhcgr1* and *lhcgr2*) in some fish species, including the European eel. European eel *lhcgr1* corresponds to the LHCGR previously characterized in the Japanese eel (*Anguilla japonica*) (Kazeto et al, 2012). In comparison to the many studies on FSH and LH, knowledge about their receptors in teleost species is still limited.

Sex steroids, such as estrogens, are also well-known for their role in reproductive function. In female fish, estrogens (primarily estradiol-17β, E2) are involved in the regulation of oogenesis and vitellogenesis (Wallace, 1985) as well as in the feedback control of gonadotropin expression and release (Zohar et al., 2010). Estrogens can diffuse through the cell membrane and bind to nuclear estrogen receptors (ESRs). Two distinct subtypes of nuclear ESRs, *esr1* and *esr2*, have been cloned from several mammalian and non-mammalian vertebrates (Mosselman et al. 1996; Hawkins et al., 2000). In teleosts, including the European eel, two paralogs of *esr2* have been reported, *esr2a* (also named *erβ2*) and *esr2b* (also named *erβ1*) (Hawkins et al., 2000; Ma et al., 2000; Menuet et al., 2002; Nagler et al., 2007; Lafont et al., 2016). In addition, estrogens can also activate receptors on the cell surface, initiating rapid and often non-genomic biological responses (Watson and Gametchu, 1999; Falkenstein et al., 2000; Norman et al., 2004). The human G-protein coupled receptor 30 (GPER30 or GPER) was shown to have the binding characteristics of an E2 membrane receptor (Revankar et al.,

84 2005; Thomas et al., 2005). Subsequent studies in zebrafish, Atlantic croaker (*Micropogonias*

85 *undulatus*) and common carp (*Cyprinus caprio*) have also shown that estrogens produced by follicle

86 cells inhibit or delay spontaneous follicular maturation via the activation of membrane receptors (Pang

87 et al., 2008; Pang and Thomas, 2009; Peyton and Thomas, 2011; Majumder et al., 2015). In the

88 European eel and some other teleosts, two paralogous *gper* genes (*gpera* and *gperb*) have been recently

89 identified (Lafont et al. 2016) but their roles have not yet been investigated.

90 During follicular maturation, cytological changes in the oocytes take place. This includes migration of

91 the germinal vesicle towards the oocyte periphery followed by breakdown of the nuclear envelope, and

92 meiotic resumption (Lubzens et al., 2017). In many teleosts, including the eel, another feature of oocyte

93 cytoplasmic maturation is the coalescence of lipid droplets to form one or a few large oil globules

94 (Kagawa, 2013). These cytological changes have been used as biomarkers for assessment of oocyte

95 maturational status in relation to assisted reproduction of eel (Palstra et al., 2005; Unuma et al., 2011).

96 The main objective of this study was to assess the expression of gonadotropin receptors (*fshr*, *lhcgr1*

97 and *lhcgr2*) and estrogen receptors (*esr1*, *esr2a*, *esr2b*, *gpera and gperb*) during induced maturation

98 and ovulation and investigate their relation with subsequent egg quality, ultimately estimated as

99 fertilization rate, hatching success and early larval survival. Finally, concomitant changes in oocyte

100 lipid droplet size were evaluated as potential cytological biomarker of follicular maturational status.

101 **2   Materials and Methods**

102 *2.1   Ethics statement*

103 All fish were handled in accordance with the European Union regulations concerning the protection of

104 experimental animals (Dir 86/609/EEC). Eel experimental breeding protocols were approved by the

105 Animal Experiments Inspectorate (AEI), Danish Ministry of Food, Agriculture and Fisheries (permit

106 number: 2010/561-1783). All efforts were made to minimize animal handling and stress.

107 *2.2   Experimental animals and rearing conditions*

108 Female silver eels (n=10; mean length and weight ± SD were 72 ± 11 cm and 781 ± 393 g,

109 respectively) were caught from a freshwater lake (Vandet Sø) in northern Jutland (Denmark) and

110 transported to a research facility of the Technical University of Denmark located at Lyksvad Fish Farm

111 (Vamdrup, Denmark). Eels were randomly distributed into duplicate 300 L tanks equipped with a

112 recirculation system and gradually acclimated to artificial saltwater over a period of two weeks, i.e.

113 freshwater adjusted to 36 ppt salinity using Tropic Marin Sea Salt (Dr. Biener GmbH, Wartenberg,

114 Germany). Thirty male eels (body weight 106 ± 13 g; body length 38 ± 2 cm) reared on DAN-EX

115 2848 (BioMar A/S, Brande, Denmark) were obtained at a commercial eel farm (Stensgård Eel Farm

116 A/S, Randbøl, Denmark), transported to Lyksvad Fish Farm and kept in separate tanks under the same

117 conditions as the female eels. At the onset of hormonal treatment, the eels were anaesthetized

118 individually in an aqueous solution of benzocaine (ethyl p-aminobenzoate, 20 mg/L, Sigma-Aldrich,

119 Germany), tagged with a passive integrated transponder (pit-tag) in the abdominal muscle, and body

120 weight and length were measured**.** Throughout the experiment, all fish were maintained at ~36 ppt

121 salinity, ~20 °C, and a natural local daily photoperiod. No feed was provided during experiments since

122 eels in the migratory, silvering stage cease feeding (Lokman et al., 2003).

123 *2.3   Induction of gametogenesis and sampling*

124 Females received weekly intramuscular injection of salmon pituitary extract (SPE) at a constant dosage

125 of 18.75 mg/kg initial body weight to induce and sustain follicular development and vitellogenesis

126 (Kagawa et al., 2005; Tomkiewicz et al., 2012). The first injection was given concurrent with pit-

127 tagging and regular treatment lasted 16-20 weeks depending on the responsiveness of the females.

128 Pituitary extract was prepared using freeze-dried salmon pituitaries (Argent Chemical Laboratories,

129 Washington, USA) that were grinded, diluted in NaCl 0.9 g/L and centrifuged according to Ohta et al.

130 (1996, 1997). Supernatants were stored at -20 °C until use. Females were weighed at the weekly

131 injections to follow changes in body weight.

132 Individual treatment for follicular maturation and ovulation was initiated at first signs of the onset of

133 oocyte hydration, i.e. a body weight increase of $10 - 15$ % compared to the initial weight and a soft

134 abdomen (Pedersen, 2003, 2004). To assess oocyte developmental stage, each female was

135 anaesthetized in an aqueous solution of benzocaine, and an ovarian biopsy (~0.2 ml) was obtained,

136 using a sterile disposable injection needle (16G x 1 ½"). The biopsy was taken at a standard location on

137 the left side of the body ~5 - 10 cm anterior to the genital pore, relative to female size, and the female

138 thereafter transferred to a separate tank under the same conditions for individual care. The biopsy was

139 inspected under the microscope and oocyte development graded on a scale from 1-7 according to

140 Palstra et al. (2005). Progression of oocyte maturation varied in time and homogeneity, so each female

141 was followed until the most developed oocytes exhibited characteristics close to stage 4, i.e., fully

142 transparent oocyte with nucleus at periphery (Fig. 1). At this stage, an additional SPE injection as

143 primer was given to females to sustain and boost follicular development (Pedersen, 2004; Kagawa et

144 al., 2005). To complete follicular maturation and induce ovulation, the eel maturation inducing steroid,

145 17α, 20β-dihydroxy-4-pregnen-3-one (DHP crystalline, Sigma-Aldrich Chemie, Steinheim, Germany)

146 was given ~24 h later at a dose of 2 mg/kg present body weight (Ohta et al., 1996). Prior to DHP

147 injection, a new biopsy (~0.2 ml) was obtained to evaluate the progression of oocyte development.

148 DHP was injected into the ovarian tissue under anaesthesia (Palstra et al. 2005). Female eels ovulated

149 12 to 15 hours after DHP injection and at that time the eggs were stripped by applying gentle pressure

150 along the abdomen of the fish. The volume of ovulated eggs collected was recorded.

151 Induction of spermatogenesis in the male eels started 4 weeks after the induction of oogenesis in

152 females, as males only need 7-9 weeks of treatment to reach spermiation (Tomkiewicz et al. 2011).

153 Each week, males received an intramuscular injection of human chorionic gonadotropin (hCG, Sigma

154 Aldrich Denmark, A/S) at dose of 1.5 IU hCG per kg initial body weight (Butts et al., 2014). An

155 additional hCG injection was given 12 h prior to milt collection in order to enhance sperm production.

156 *2.4   Sampling for gene expression and cytological analysis*

157 Sampling for each female comprised: 1) the ~0.2 ml ovarian biopsy obtained ~1h before the SPE

158 priming injection (SPE); 2) the ~0.2 ml biopsy obtained prior to DHP injection (DHP) and 3) a sample

159 of unfertilized eggs collected immediately after stripping (EGG). Each sample included digital images

160 of oocytes/eggs to measure lipid droplet diameter and a preserved sample (~0.1 ml) for gene expression

161 analysis. Prior to photography, the sampled oocytes/eggs were cleared in Serra's liquid

162 (ethanol:formalin:acetic at 6:4:1, diluted 20X in phosphate buffered saline, PBS, see Stoeckel (2000))

163 for staining of the germinal vesicle. The pictures were taken at 20X magnification using a digital

164 camera (Digital Sight DS-Fi1, Nikon Corporation, Japan) connected to an optical microscope (Eclipse

165 55i, Nikon Corporation, Japan) for measurement of lipid droplet diameter inside the oocytes. Samples

166 taken for analysis of gene expression were preserved in RNA-later (Ambion Inc., Huntingdon, UK),

167 refrigerated at 5 °C for 24 h and then frozen at -20 °C until RNA extraction.

168 *2.5 Fertilization rate, hatching success and larval survival*

169 In order to evaluate the egg viability, eggs were fertilized *in vitro*, and fertilization rate, hatching

170 success, and larval survival was determined. For each female, milt from 4-5 males was collected,

171 leaving three week intervals between individual male stripping. The spermatocrit was estimated

172 (pooled milt mixture according to Sørensen et al. (2013) and used to dilute milt in an immobilizing

173 diluent (Asturiano et al., 2004; Peñaranda et al., 2010). The diluted milt at a standardized concentration

174 was used for fertilization within 4 hours after collection (Butts et al., 2014).

175 Immediately after stripping, eggs were mixed with the milt solution and added natural seawater for

176 sperm activation (Butts et al. 2014). After 5 min gamete contact time, a sub-sample of eggs was

177 transferred to a 100 ml graduated cylinder glass to estimate percent floating eggs. The remaining eggs

178 were transferred to 10 L containers for separation of floating and sinking eggs. The eggs were kept at

179 20 °C and the fertilization rate and floating percent was accessed 3-5 hours post fertilization (HPF). To

180 estimate fertilization success, a sample of 100-150 floating eggs was photographed using an optical

181 microscope (Eclipse 55i, Nikon Corporation, Japan) at 20X magnification and a digital camera (Digital

182 Sight DS-Fi1, Nikon Corporation, Japan). Fertilized eggs were identified by the presence of blastomere

183 cleavage (minimum 4 cell stage), while those that had not reached the 4-cell stage were considered

184 unfertilized.

185 For estimation of hatching success, eggs (~200 eggs in triplicate, for each female) were collected from

186 the floating layer after 3-5 HPF and incubated at 20 °C in flasks (Nunc® 75 cm2 flasks, non-treated

187 with ventilated caps, Thermo Scientific) (Sørensen et al. 2014). Each flask contained 250 ml of

188 seawater (36 ppt) ampicillin (50 mg/L) and rifampicin (50 mg/L). Flasks stayed undisturbed inside a

189 dark and closed incubator at 20 °C until the number of hatched larvae was counted at 55 HPF. To

190   estimate larval survival, ~300 g of eggs from the floating layer were incubated in a 60 L incubator with

191   natural seawater at ~20 °C. After hatch, when available ~3000 larvae in triplicate were stocked in 40 L

192   tanks of an aquaculture recirculation system containing natural seawater adjusted to 36 ppt salinity

193   using Tropic Marin Sea Salt and reared at 20 °C. Survival was measured as the percentage of still

194   living larvae at 3 days post hatch (dph).

195   For statistical analysis, egg batches were categorized into two groups: i) high-quality and ii) low-

196   quality based on larval survival. Hereby, survival beyond the first 3 dph (high mortality period) was

197   used to differentiate the groups (Table 2).

198   *2.6   Gene expression analysis*

199   RNA extraction and cDNA synthesis:

200   After Proteinase K treatment, total RNA was purified from ovarian biopsies and ovulated eggs by

201   homogenization of 30 mg of tissue in 700 µl TRIzol reagent (Invitrogen Life Technologies, Carlsbad,

202   CA, USA). TRIzol/chloroform separation was performed to remove DNA and proteins. The aqueous-

203   phase was transferred to a new tube and 500 µl of isopropanol were added for RNA precipitation.

204   Genomic DNA contamination was removed by treating the total RNA with the TURBO DNA-free kit

205   (Ambion). Total RNA quality and concentration was measured spectrophotometrically using

206   NanoDrop (Saveen Werner AB, Limhamn, Sweden).

207   RNA was then reverse transcribed into cDNA using Hight Capacity RNA-to-cDNA kit (AB) according

208   to manufacturer's protocol. In summary, reaction volumes of 20 µl contained 450 ng total RNA, 1X RT

209   buffer, 1X enzyme mix. The following cycling parameters were used: 37 °C for 60 min, 95 °C for 5

210   min and hold at 4 °C, using a 2720 Thermal cycler, AB.

211   Quantitative real-time PCR (qPCR):

212   The following gene specific primers were previously designed based on the nucleotide sequence of the

213   European eel: gonadotropin receptors, *fshr, lhcgr1* and *lhcgr2* (Maugars and Dufour, 2015); estrogen

214   receptors, *esr1*, *esr2a*, *esr2b*, *gpera and gperb* (Lafont et al., 2016). Specific primers for European eel

215   18S ribosomal RNA gene (*18S*) were designed in this study (Table 1), and their specificity and

216   efficiency was tested in qPCR.

217   The qPCRs were performed with a lightcycler (Roche, Ltd. Basel, Switzerland), using SYBR Green I.

218   Each reaction was prepared with 4 µl of diluted cDNA template, 2 µl PCR grade water, 2 µl of SYBR

219   Green master mix and 1 µl of each forward and reverse primers (0.5 pmol each at final concentration).

220   The following qPCR conditions were applied: polymerase activation step of 10 min at 95 °C, followed

221   by 51 cycles of 10 sec of denaturizing at 95 °C, 5 sec of annealing at 60 °C, 6 sec of elongation at 72

222   °C for *esr1*, *esr2a*, *esr2b*, *gpera and gperb* or 10 sec at 72 °C for *18S*, *lhcgr1*, *lhcgr2* and *fshr*. The

223   programs ended with a melting curve analysis by slowly increasing the temperature (0.1 °C/sec) from

224   65 °C to 95 °C, with a continuous registration of changes in fluorescent emission intensity. This last

225   step aimed at ensuring the presence of only one amplified product. Each qPCR run contained a non-

226   template control (cDNA was substituted by water) for each primer pairs to confirm that the qPCR mix

227   was not contaminated. Serial dilutions of a pool of ovary biopsies and ovulated egg cDNAs were used

228   as a standard curve for each gene. One dilution was included in each run as a calibrator. Normalization

229   of the qPCR data was performed using *18S* as a reference gene since it was stable through all sampling

230   points with a coefficient of variance at SPE, DHP and OV of 40%, 40% and 48%, respectively.

231 *2.7   Measurement of lipid droplet diameter*

232 Using the digital images of each sample (before SPE priming, before DHP injection and ovulated

233 eggs), 10 oocytes were randomly selected among those at the most advanced stage of development.

234 Here, ten of the largest lipid droplets were measured using the free software ImageJ (1.48d) and the

235 maximum five values averaged (Unuma et al., 2011). For each lipid droplet, the diameter was

236 calculated by the average of two diameter measurements. At the final stages of coalescence, only a few

237 droplets became larger while the others became smaller (Fig. 1), in these stages, the diameter was

238 based on the diameter of the largest droplets only (Unuma et al., 2011).

239 *2.8   Statistical analysis*

240 Statistical analysis was performed using R version 3.1.3 (R core team, 2015). Statistical differences in

241 gene expression and lipid droplet diameter between quality groups (high- and low-quality) in relation to

242 sampling time (before SPE, before DHP and after stripping) were evaluated using linear mixed-effects

243 (LME) models. The female ID was included in the models as within-subjects variable to account for

244 the repeated measurements taken on each female through the sampling points. Model assumptions of

245 normality and equal variance were checked using Q-Q plots and by observation of the residuals versus

246 fitted values plot. Square root and logarithmic transformations were applied to gene expression and

247 droplet diameter data whenever data deviated from a normal distribution. Linear regression analysis

248 was used to determine whether there were significant correlations between gene expression at each

249 sampling time and fertilization rate and hatching success. The expression of each gene was screened for

250 outliers using the Tukey's method. This method uses the interquartile range (IQR) to identify the

251 outliers range above and below the 1.5X IQR. A significance level (p) of 0.05 was applied in all tests.

252 **3 Results**

253 3.1 Egg production, fertilization and hatching success

254 The females studied produced on 327 ± 152 g eggs corresponding to 29-56 % of the initial body weight

255 (Table 2). The percent floating eggs varied from 25 to 100 %, while the fertilization rate ranged

256 between 15 to 99 % and the hatching rate between 0 to 80 %. Batch size was positively related to initial

257 female body weight (R = 0.94; $p < 0.001$) and length (R = 0.95; $p < 0.001$). Fertilization rate was not

258 correlated with female length (R = -0.03; $p = 0.930$) nor initial weight (R = 0.09; $p = 0.798$). Hatching

259 success ranged from 19 to 80 % and 0 to 5 % in the high- and low-quality groups, respectively (Table

260 2). There was also no significant correlation between hatching success and female length (R = -0.03; p

261 $= 0.927$) nor initial weight (R = 0.05; $p = 0.901$).

262 3.2 Expression of gonadotropin receptors

263 All three gonadotropin receptors (*fshr, lhcgr* and *lhcgr2*) were detected in the ovarian biopsies with

264 genes differentially expressed across sampling points from the induction of oocyte maturation, SPE and

265 DHP, and EGG (Fig. 2). Overall, transcript levels of *fshr* did not vary during oocyte maturation, i.e.

266 between the ovarian biopsy taken before SPE and the biopsy taken before DHP ($p > 0.05$). However,

267 *fshr* levels dropped down below the level of detection of qRT-PCR detection in the eggs (at least 534

268 times less expressed than in the ovarian biopsies). Within sampling points, the expression levels of *fshr*

269 were similar between the high- and low-quality groups in the biopsies obtained prior to SPE priming (p

270 > 0.05; Fig. 2). However, before DHP, *fshr* transcript levels were significantly lower in the high-quality

271 group than in the low-quality group ($p < 0.001$). Present results also indicated a significant negative

272 correlation between *fshr* before DHP injection and hatching success (R = -0.79; $p = 0.012$; Table 3).

273   Overall, *lhcgr1* mRNA levels did not vary significantly ($p > 0.05$) during maturation (from SPE to

274   DHP injection). In contrast, transcript levels were around 150 times lower in ovulated eggs than in the

275   ovarian biopsies ($p < 0.001$). Moreover, in the ovarian biopsies collected before SPE priming, *lhcgr1*

276   expression was significantly higher in the high-quality group compared to the low-quality (*p*

277    $= 0.002$; Fig. 2). Present results also showed a significant positive correlation between *lhcgr1* at SPE

278   and hatching success (R $= 0.68$, $p = 0.032$; Table 3). There was no difference between the two groups

279   in the ovary samples taken before DHP injection and in ovulated eggs ($p > 0.05$).

280   Regardless of egg quality, *lhcgr2* transcript levels were similar between the ovarian biopsies taken

281   before SPE and DHP ($p > 0.05$) but significantly less expressed in the ovulated eggs (at least 5 times

282   less expressed than in the ovarian biopsies, $p < 0.001$). Within sampling points, transcript levels of

283   ovarian *lhcgr2* at SPE priming and DHP injection did not differ significantly between the high and low

284   quality groups ($p > 0.05$; Fig. 2). However, *lhcgr2* mRNA levels in unfertilized egg samples were

285   significantly higher in the high-quality than in the low-quality group ($p = 0.013$). There were no

286   significant correlations between *lhcgr2* transcript levels and hatching success or fertilization rate (*p* >

287   0.05; Table 3).

288   3.3   Expression of estrogen receptors

289   The nuclear receptor *esr1* was expressed in the ovarian samples obtained during oocyte maturation

290   without significant variation between the ovarian samples before SPE priming and DHP ($p > 0.05$; Fig.

291   3). After stripping, transcript levels were below the level of detection of qRT-PCR in unfertilized eggs

292   (at least 40 times less expressed than in the ovarian biopsies). Moreover, *esr1* expression was similar

293   between the high- and low-quality groups within the SPE and DHP sampling points ($p > 0.05$). There

14

294   were no significant correlations between *esr1* and hatching success or fertilization rate ($p > 0.05$; Table

295   3).

296   From the two nuclear *esr2* receptors, only *esr2a* was detected in the ovary during the induction of

297   oocyte maturation. Irrespective of hatching success, transcript levels of *esr2a* did not vary during

298   maturation treatment ($p > 0.05$), but the gene was much less expressed in unfertilized eggs (at least 67

299   times less expressed than in the ovarian biopsies, $p < 0.001$). In the biopsies taken before SPE priming,

300   transcript levels of *esr2a* were significantly higher in the high-quality group compared to the low-

301   quality group ($p = 0.020$; Fig. 3). In the ovarian biopsies taken before DHP and ovulated eggs, *esr2a*

302   expression levels were similar between groups ($p > 0.05$). We did not find any significant correlations

303   between *esr2a* transcript levels and hatching success or fertilization rate ($p > 0.05$; Table 3). Transcript

304   levels of *esr2b* were below the qRT-PCR detection threshold in all samples and could not be measured.

305   The two estradiol membrane receptors, *gpera* and *gperb,* were detectable and presented a different

306   expression pattern during induced oocyte maturation and after stripping (Fig. 3). Irrespective of egg

307   quality group, *gpera* transcript levels did not vary during maturation treatment ($p > 0.05$) but were

308   significantly lower in the eggs ($p < 0.001$). Expression of *gpera* did not differ significantly between

309   high- and low-quality in neither the ovarian biopsies before SPE and DHP injection, nor in ovulated

310   eggs ($p > 0.05$; Fig. 3). There were no significant correlations between *gpera* transcript levels and

311   hatching success or fertilization rate ($p > 0.05$; Table 3). Overall, there was no significant difference in

312   *gperb* mRNA expression levels during maturation ($p > 0.05$) while transcript levels of *gperb* dropped

313   to a level below the qRT-PCR detection threshold in ovulated eggs (at least 375 times less expressed

314   than in the ovarian biopsies). The expression levels of *gperb* before SPE administration did not differ

315   between the high-quality and low-quality group ($p > 0.05$) while levels were significantly lower in the

316   high-quality before the DHP administration ($p = 0.010$; Fig. 3). Present results did not show any

317   significant correlations between *gperb* levels and hatching success or fertilization rate ($P > 0.05$; Table

318   3).

319   3.4   Lipid-droplet related oocyte maturation status

320   Image analysis of the ovarian biopsies collected during the course of oocyte maturation induction

321   revealed 2-3 cohorts of oocytes of different sizes and stages of development (Fig. 4). Oocytes at the

322   most advanced stage of development were at the germinal vesicle migration stage, characterized by a

323   transparent cytoplasm and peripheral germinal vesicle visible before SPE and DHP injection (Fig. 1a

324   and b), similar to stage 4 and 5 according to the classification developed by Palstra et al. (2005),

325   respectively. No germinal vesicle could be observed in ovulated eggs after clearing in Serra's liquid

326   (Fig. 1c). As lipid droplets coalesced, their diameter increased significantly throughout oocyte

327   maturation and stripped eggs ($p < 0.001$). In the high-quality group, mean ± SD lipid droplet diameter

328   was 89 ± 23 µm at SPE priming, 136 ± 14 µm at DHP injection and 156 ± 15 µm at EGG. In the low-

329   quality group, lipid droplet diameter was 110 ± 34 µm at SPE priming, 194 ± 72 µm at DHP injection

330   and 248 ± 74 µm at EGG. Overall, mean lipid droplet diameter was significantly higher and with wide

331   size variations in the low-quality than in the high-quality group ($p = 0.028$; Fig. 5), and mean size

332   increased significantly over time in both groups (from SPE to EGG, $p < 0.001$). Lipid droplet size in

333   the low-quality group also demonstrated an increasingly larger inter-female size variation over time,

334   compared to the high-quality group, where there were less lipid droplet size variation at all times. We

335   did not find a significant difference in droplet diameter between high- and low-quality at SPE priming

336   ($p > 0.05$) but at DHP and EGG, lipid droplet diameter was significantly higher in the low-quality

337   group ($p = 0.042$ and $p = 0.005$, respectively).

4   Discussion

4.1   Differential expression of gonadotropin receptors

Gonadotropin receptors mediate the biological effects exerted by gonadotropin hormones. In this study, we analyzed for the first time the expression pattern of the *fshr* and the duplicate *lhcgr* during the induction of follicular maturation and ovulation of European eel using SPE treatment. The expression of the two genes encoding distinct LHCGR (*lhcgr1* and *lhcgr2*) was also detected in the ovary of immature eels (Maugars and Dufour, 2015). In the present case, both *lhcgr1* and *lhcg2* were well expressed in the ovary during induced maturation. Since the report of the coexistence of duplicated *lhcgr* in teleosts (Maugars and Dufour, 2015), their expressions have not yet been compared in any other teleost species. In fishes, there are few studies about the expression of gonadotropin receptors during follicular maturation and ovulation and none concerning gonadotropins and estradiol receptors multiple paralogs. A previous study showed a high expression of ovarian *lhcgr* orthologous to eel *lhcgr2*, in mature female Atlantic salmon (*Salmo salar*) caught during the upstream migration (Maugars and Schmitz, 2006), which appears characteristic of the maturation stage prior to ovulation. Moreover, we found that both genes were significantly less expressed in ovulated eggs. This agrees with the location of LH binding sites found in the granulosa and thecal cells in European eel (Salmon et al., 1988). Similarly, *lhcgr* orthologous to eel *lhcgr1* was found to be expressed in granulosa and weakly in theca cells in chub mackerel (*Scomber japonicus*) (Nyuji et al., 2013) and Atlantic halibut (*Hippoglossus hippoglossus*) (Kobayashi et al., 2008). Therefore, a drop in mRNA levels would be expected in successfully ovulated eggs due to the loss of the follicle layers that remain inside the ovary after the oocyte is extruded. Nevertheless, the drop in expression in ovulated eggs was more substantial for *lhcgr1* (150 less expressed) than for *lhcgr2* (5 times less expressed), suggesting that *lhcgr1* is mostly expressed in follicular cells.

361 We hypothesized that differences in responsiveness to hormonal treatments during oocyte maturation

362 may be related to differences in hormone receptor expression, which consequently could affect

363 embryonic development. To test this, we calculated hatching success and larval survival as measures of

364 embryonic developmental competence (egg quality). Transcript levels of *lhcgr2* during induction of

365 oocyte maturation were similar regardless of hatching success. However, *lhcgr2* mRNA in ovulated

366 eggs was significantly higher in the high-quality group when compared to the low-quality group,

367 suggesting that *lhcgr2* could have a role in embryonic development. Gonadotropin receptor transcripts

368 are also present in mouse oocyte and preimplantation embryo, with a potential beneficial role in oocyte

369 maturation and early embryonic development (Patsoula et al., 2001).

370 Previous studies have shown that gonadotropic treatment induces an increase in mRNA levels of *lhβ* as

371 well as an increase in LH hormone in the pituitary in both European (Dufour et al., 1989; Schmitz et

372 al., 2005) and Japanese eel (Nagae et al., 1996; Saito et al., 2003; Jeng et al., 2007). This increase in

373 pituitary content of LH is likely necessary for the LH surge (in this case mimicked by the LH present in

374 the SPE) triggering ovulation. However, it is still uncertain if this observation is due to the effect of

375 gonadotropins alone, as both SPE and CPE treatments contain other components (neurotransmitters,

376 steroids) that can affect receptor expression. Our results showed that ovarian levels of *lhcgr1* at the

377 time of SPE primer administration were both positively correlated with hatching success, and were

378 significantly higher in the high-quality group than in the low-quality group at SPE. This suggests that

379 females with higher hatching success had higher sensitivity to LH at the time SPE was administrated.

380 In contrast, the significantly lower levels of *lhcgr1* expression in females with low-quality eggs could

381 have limited their response to the LH in the SPE primer. This is particularly important, in a first stage

382 of oocyte maturation, LH regulates the follicle's ability to produce maturation-inducing steroid (MIS)

383 and the oocyte's response to MIS (i.e. oocyte maturational competence); on a second stage the follicle

384 cells produce MIS (Patiño et al., 2001). Thus, failure to respond to LH at the first stage could

385 subsequently compromise the oocyte's ability to respond to the MIS (i.e. the DHP injection).

386 Additionally, LH signalling can stimulate other pathways than those leading to DHP synthesis. This has

387 been observed in zebrafish, where the expression of *ptgs2a* (a cox-2 gene) induced by LH was

388 necessary for ovulation to occur (Tang et al., 2017). Since oocyte maturation and ovulation may be

389 independently/differently regulated by the same ligand, the two processes may come out of synchrony

390 with each other, and this may influence the developmental capacity of the egg/embryo. In this case, the

391 mismatch between *lhcgr1* expression and the administration of the SPE primer may have affected the

392 follicle's ability to respond to DHP in females in the low-quality group. Hence, a high expression of

393 *lhcgr1* before SPE priming seems to be a good biomarker of high maturational competence.

394 Overall, *fshr* was well expressed in the mature ovary at all sampling times during the induction of

395 oocyte maturation. In Japanese eel, 17 weeks of treatment with pituitary homogenates also increased

396 ovarian levels of *fshr* (Jeng et al., 2007). However, the physiological relevance of high *fshr* expression

397 during ovarian maturation in teleosts is still unclear. In the case of the eel, gonadotropins contained in

398 exogenous pituitary homogenates (SPE in this case) could up-regulate the expression of both

399 gonadotropin receptors. Alternatively, in the case of multiple spawning, an ovulatory surge of FSH

400 could play an important role in the follicle recruitment for the next reproductive cycle (Prat et al., 1996;

401 Tyler et al., 1997; Sambroni et al., 2007). In this study, oocyte development presented a group-

402 synchronous pattern (Wallace and Selman, 1981), with 2-3 cohorts of oocytes of different size and

403 stage of development present in the ovarian biopsies taken during the induction of oocyte maturation

404 and ovulation. Thus, a high expression of *fshr* in the ovary during maturation could be related to the

regulatory role of FSH on the less developed oocyte batches also present in the biopsies. Alternatively, it is also possible that FSHR has an important function on maturing oocytes (as occurs in mammals, where FSH up-regulates LHCGR (Zeleznik et al., 1974). After ovulation, levels of *fshr* mRNA level dropped below the level of detection, indicating that *fshr* is also mostly expressed in the follicle cells surrounding the oocyte. This is in agreement with the observations by *in situ* hybridization of *fshr* expression in granulosa and theca cells in vitellogenic follicles in salmon (Andersson et al., 2009).

In relation to hatching success, present results showed that transcript levels of *fshr* before the DHP injection were negatively correlated with hatching success, and females with low quality eggs had significantly higher transcript levels of *fshr*. This indicates that females in the low-quality group were more sensitive to FSH at the time DHP was administrated. However, while *lhβ* mRNA levels tend to increase, *fshβ* levels significantly decrease with gonadotropic treatment in both Japanese (Yoshiura et al., 1999) and European eel females (Schmitz et al., 2005). Therefore, increased sensitivity to FSH at the time of DHP injection does not appear to be determinant for successful oocyte maturation and ovulation treatment in European eel. In contrast, increasing mRNA levels of *fshr* were associated to a better competence of the oocyte to mature following pituitary hormone induction in rainbow trout (*Oncorhynchus mykiss*) (Bobe et al., 2003). However, differences in hormone receptor expression among species are likely influenced by differences in the reproductive strategies. For example, in rainbow trout which is considered as total spawner (Mylonas and Zohar, 2007), *fshr* mRNA levels peak at maturation and ovulation while *lhcgr* increased significantly later after ovulation (Sambroni et al., 2007). In contrast, in zebrafish, which is a multiple batch spawner, *fshr* transcripts peaked at mid-vitellogenesis and dropped at the end of vitellogenesis (Kwok et al., 2005). Overall, a combination of low expression of ovarian *lhcgr1* before SPE priming and high expression of *fshr,* when DHP is

427 administrated, could be indicators of an ineffective response to oocyte maturation treatment resulting in

428 low egg quality.

429 4.2 Differential expression of estrogen receptors

430 In this study, we quantified gene expression of three nuclear (*esr1*, *esr2a*, *esr2b*) and two membrane

431 (*gpera* and *gperb*) estrogen receptors, during hormonal induction of oocyte maturation in European eel.

432 We found that transcripts of *esr1* were quite similar in the eel ovary throughout induced maturation,

433 with no significant differences between the two hatching groups. This suggests that *esr1* mRNA is not

434 a limiting factor for the development of maturational competence. Nevertheless, up-regulation of *esr1*

435 transcripts in the ovary of matured eels after ovulation (Lafont et al, 2015) suggests that this receptor

436 might play an important role during oocyte maturation. Regulation of *esr1* transcript levels may be

437 associated with an increase in circulatory levels of estradiol-17β (E_2) during oocyte maturation stages

438 (da Silva et al., 2016). In particular, E_2 plasma concentration increases two to five times after SPE

439 priming in European eel (H. Tveiten, unpubl. results). Up-regulation of *esr1* was associated with an

440 increase of circulatory estrogens before ovulation also *in vitro* in eel hepatocytes (Lafont et al, 2015).

441 In contrast, *esr1* expression in the testis of male eels was markedly expressed in early stages of

442 spermatogenesis but significantly down-regulated in late stages of spermatogenesis (Morini et al.,

443 2017). This indicates a differential expression pattern of *esr1* between oogenesis and spermatogenesis

444 in eels. Differences in hepatic *esr1* expression between sexes have been observed in goldfish and are

445 likely related to differences in basal levels of E_2 between males and females (Nelson and Habibi, 2010).

446 In unfertilized eggs, *esr1* transcript levels were below the level of detection, suggesting that this

447 estrogen receptor is mostly expressed in the follicular cells.

448   Before SPE priming, *esr2a* transcripts were significantly more expressed in females with higher

449   hatching success which may indicate that this receptor has an important role during oocyte maturation.

450   In previous studies, the expression of *esr2a* in mature female eels after spawning was similar to

451   controls (Lafont et al., 2015) and in male eels, it was down-regulated during final stages of

452   spermatogenesis (Morini et al., 2017). Transcripts of *esr2a* were below the level of detection of the

453   qRT-PCR in ovulated eggs, suggesting that they are mainly expressed in follicular cells, as *esr1*.

454   Transcripts of *esr2b* were below the level of detection of the qRT-PCR in all samples, i.e. undetectable

455   during follicular maturation and ovulation. In male eels, *esr2b* transcripts in the testis were significantly

456   down-regulated throughout spermatogenesis (Morini et al., 2017). Thus, it is likely that *esr2b* does not

457   play a key role during the final stages of gametogenesis in European eel.

458   It is well known that in female fish GPER mediates the E_2-induced meiotic arrest of oocytes, e.g.

459   zebrafish, Atlantic croaker and common carp (Majumder et al., 2015; Pang and Thomas, 2009; Pang et

460   al., 2008; Peyton and Thomas, 2011). In these previous studies, only one GPER gene was

461   characterized, known now to be the orthologous to teleost *gpera*. We found that *gpera* transcripts were

462   expressed at similar levels in the ovary throughout the oocyte maturation (all stages), without

463   significant differences between the high-quality and low-quality group. Levels of *gpera* transcript

464   showed only a moderate decrease in ovulated eggs (not significant), indicating that *gpera* transcripts

465   are largely present in the eel oocyte itself, in contrast to all the other estradiol receptors. In contrast,

466   expression of *gperb* before DHP injection was significantly lower in females exhibiting higher egg

467   viability. Furthermore, *gperb* was the only estrogen receptor that was less expressed in females

468   exhibiting high quality eggs. This may suggest that *gperb* plays an important role in mediating the

469   inhibitory effect of estrogen during oocyte maturation also in European eel, where estrogen-dependent

470   oocyte growth is arrested at the first meiotic prophase by high levels of intracellular cyclic AMP

471   (cAMP) (Conti et al., 2002). In the pre-ovulatory phase, a LH surge causes a shift in the steroidogenic

472   pathway to the production of the MIS. When the MIS production (DHP injection in this case) is

473   sufficient to overcome the estrogen inhibitory effect, the binding of MIS to a G protein-coupled

474   progestin membrane receptor triggers meiosis resumption and GVBD by causing a decrease in cAMP

475   concentrations (Jalabert and Finet 1986; Finet et al., 1988). Moreover, in Japanese eel, increased E_2 in

476   the late stages of oocyte development inhibits the production of DHP (Ijiri et al., 1995). Thus, a lower

477   expression of *gperb* in the HEQ group suggests a lower sensitivity to estrogen and subsequently a

478   lower estrogen inhibition, which may have enhanced the effect of DHP. In male eels, both *gpera* and

479   *gperb* transcripts significantly increased during spermatogenesis suggesting that GPERs may be

480   involved in final sperm maturation (Morini et al., 2017). Overall, our results raise the possibility that an

481   E_2 pathway, possibly regulated by *esr2a* and *gperb,* is involved in the control of oocyte maturation also

482   in European eel. However, we did not find any significant correlation between the expression of these

483   two genes and other egg quality indicators such as fertilization and hatching success. Thus, evidence is

484   weak and further investigation is necessary to clarify their role during oocyte maturation and

485   subsequent egg quality.

486   4.3   Cytological indicators of oocyte maturation status

487   An early index of maturational acquisition is the onset of germinal vesicle migration, which is

488   accompanied by the rise in LH at the end of follicle growth (Lubzens et al., 2010). In this study, a

489   peripheral germinal vesicle in the most advanced oocytes was used as an indicator that females had

490   progressed into initial stages of oocyte maturation before SPE priming. The appearance of oil droplets

491   was used as a marker of the maturation progress to initiate SPE priming or DHP injection (Palstra et al.

492 2005; Unuma et al., 2011). Here, the coalescence of the oil droplets reflects the hormonal processes

493 during final maturation resulting in decreasing numbers and increasing size of the lipid droplets.

494 Interestingly in this study, the oocytes of females in the high-quality group had on average smaller lipid

495 droplets with less size variation compared to those with low-quality group. Especially at DHP and

496 ovulation the difference between the groups was significant. The observed variation in lipid droplet

497 size, in conjunction with the hormone receptor expression pattern in the same females, suggests that

498 treatment administrated at an earlier stage enhanced maturational competence and the subsequent

499 developmental capacity of the egg/embryo. In general, limited information is available on the

500 mechanisms of oocyte lipid coalescence as well as on the role of this physiologically important process

501 in the subsequent survival and development of the eggs and embryos. Our findings, substantiating

502 insight in the underlying hormonal processes, suggest lipid droplet diameter to be an accurate,

503 quantitative indicator of maturation status in European eel.

504 In conclusion, ovarian *fshr*, *lhcgr1, esr2a* and *gperb* were differentially expressed across sampling

505 points between females presenting high and low egg quality. A mismatch between the timing of

506 hormone injections and the expression of some of these genes may therefore influence the follicle's

507 ability to respond to treatment. Furthermore, changes in hormone receptor expression were associated

508 with changes in oocyte maturation status. Here, the average size of lipid droplets in advanced oocytes

509 was smaller in the high- compared to low-quality group throughout the maturation process, indicating

510 that the timing of hormonal treatments can be optimized, thereby optimizing procedures in assisted

511 reproduction of the endangered European eel.

738 **Legends**

739 **Figure 1: Oocytes at each sampling point.**

740 Photomicrographs showing examples of oocytes at the most advanced stage of development from the

741 biopsy samples taken a) before SPE priming, b) before DHP injection and c) ovulated eggs cleared in

742 Serra's liquid. GV: germinal vesicle and LD: lipid droplet.

743 **Figure 2: Expression of gonadotropin receptors.**

744 Boxplots representing expression of gonadotropin receptors (*fshr*, *lhcgr1* and *lhcgr2*) in ovarian

745 biopsies taken at the time of administration of the SPE primer (SPE) and DHP injection (DHP) as well

746 as ovulated eggs (EGG) in both high- (n=5) and low-quality (n=5) groups. The bold line inside each

747 box represents the median, lower and upper sides of each box represent the lower and upper quartile

748 (25% and 75%) and whiskers extend to the most extreme data point, no more than 1.5 times the

749 interquartile distance. Data points outside the boxplot are classed as "outliers". Significant differences

750 between groups are identified with "*" when $p < 0.05$; "**" when $p < 0.01$ and "***" when $p < 0.001$.

751 **Figure 3: Expression of estrogen receptors**.

752 Boxplots representing expression of nuclear (*esr1*, *esr2a*) and membrane estrogen receptors (*gpera* and

753 *gperb*) in ovarian biopsies taken at the time of administration of the SPE primer (SPE) and DHP

754 injection (DHP) as well as in ovulated eggs (EGG) in both high- (n=5) and low-quality (n=5) groups.

755 The bold line inside each box represents the median, lower and upper sides of each box represent the

756 lower and upper quartile (25% and 75%) and whiskers extend to the most extreme data point, no more

757 than 1.5 times the interquartile distance. Significant differences between groups are identified with "*"

758 when $p < 0.05$ and "**" when $p < 0.01$.

33

759 **Figure 4:**

760 Oocytes in three different maturational stages from an ovarian biopsy taken before the SPE priming

761 injection. 1: small and opaque oocytes; 2: large oocytes with darker cytoplasm; 3: large oocytes with

762 transparent cytoplasm and migratory nucleus.

763

764 **Figure 5: Lipid droplet diameter.**

765 Boxplot representing the lipid droplet diameter at the time of administration of the SPE priming (SPE)

766 and DHP injection (DHP), as well as in ovulated eggs (EGG) in both high- (n=5) and low-quality (n=5)

767 groups. The bold line inside each box represents the median, the lower and upper sides of each box

768 represent the lower and upper quartile (25% and 75%) and whiskers extend to the most extreme data

769 point which is no more than 1.5 times the interquartile distance. Data points outside the boxplot are

770 classed as "outliers". Significant differences between egg groups are identified with an "*" when $p <$
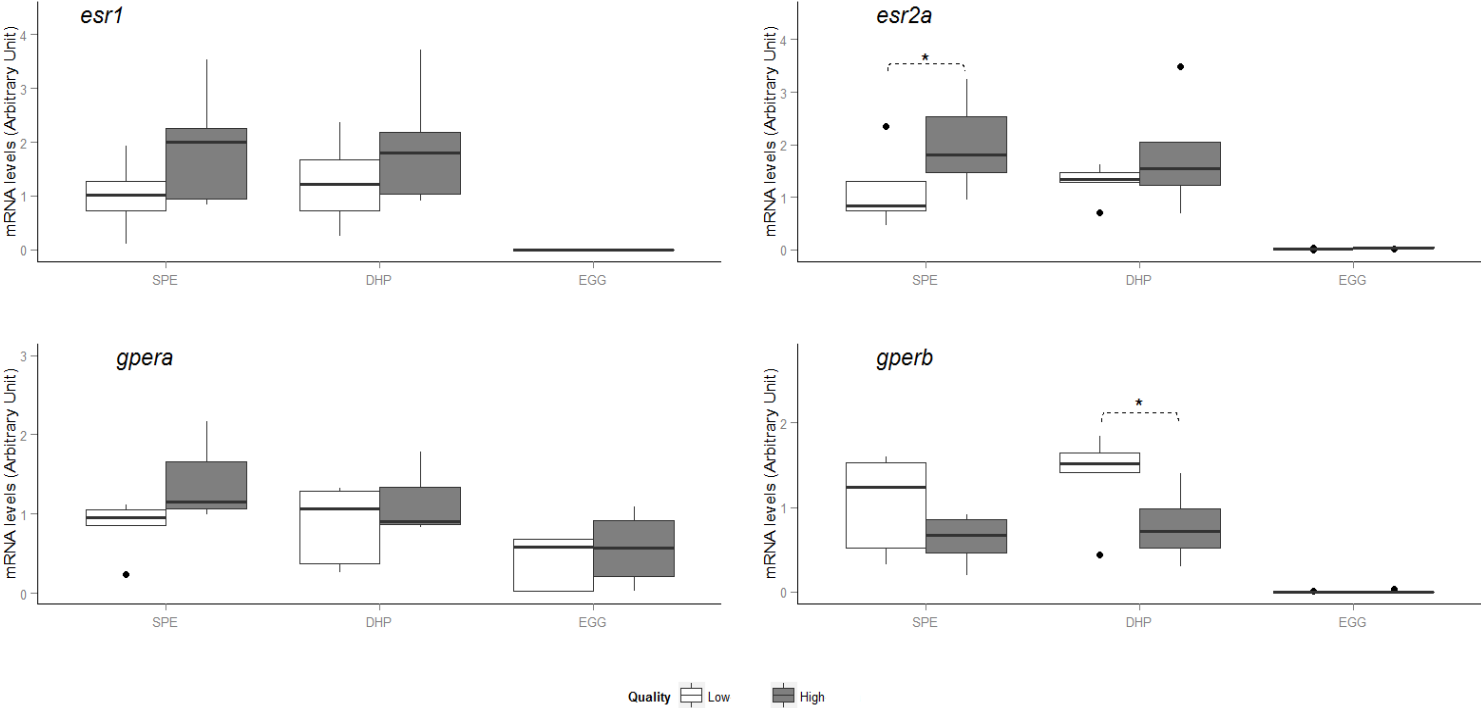

771 0.05.
