11

12 Highlights

- 13 - TDS and TCATA are compared by common and distinct components
- 14 - Common components are identified by canonical correlation analysis
- 15 - Distinct components are found after orthogonalization
- 16 - Results indicate only subtle differences between the methods
- 17 - TCATA give better discrimination of samples in all case studies

18

19 Abstract

20 Temporal Dominance of Sensations (TDS) and Temporal Check-all-that-Apply (TCATA) from three
21 different case studies are compared by means of canonical correlation analysis, orthogonalization and
22 principal component analysis of the vertically unfolded data (which means that the matrices compared
23 have samples*timepoints in the rows and attributes in the columns). The multivariate analyses
24 decompose the datasets into common and distinct components. The results showed that the major part
25 of the variation is common between the two methods for the cases investigated, but that there were
26 subtle differences showing better discrimination for TCATA than TDS. TDS showed a more complex
27 data structure and more unique variation. The unique variation in TDS is, however, difficult to interpret.
28 The methods are more different towards the end of the mastication, this can be explained both by the
29 difficulty of assessors to agree on the dominant attributes at the bolus stage for TDS, and that assessors
30 may forget to unclick attributes in TCATA. This work builds on recent methodological studies on
31 temporal methods that aim to better understand differences among methodologies and ultimately to
32 identify what methods could be better for answering different objectives.

33

34 1 Introduction

35 Sensory perception is a dynamic process as the perceived sensory characteristics of products change
36 during consumption due to several complex processes, such as chewing, breathing, salivation, tongue
37 movements and swallowing (Lawless & Heymann, 2010). Methods for tracking changes in sensory
38 perception over time have been used since the beginnings of sensory science (Holway & Hurvich, 1937;
39 Sjostrom, 1954). The first methodological approach for temporal sensory measurement was time-
40 intensity, which aims at measuring the perceived intensity of a given attribute continuously over time
41 (Lee & Pangborn, 1986). Although this methodology provides detailed information on the dynamics of
42 sensory perception, it has several drawbacks that limit its application in many situations, including its
43 time-consuming nature, differences in how assessors respond to the task, and dumping effects due to
44 attribute restriction (Lawless & Heymann, 2010).

45 To overcome these limitations, multi-attribute temporal methods that rely on the description of the
46 sensory characteristics of products over time have been developed, including Temporal Dominance of
47 Sensations (TDS) (Pineau, Cordelle & Schlich, 2003) and Temporal Check-all-that-apply (TCATA)
48 (Castura, Antúnez, Giménez & Ares, 2016). In TDS, assessors evaluate the temporal sensory profile of
49 products by identifying the dominant attribute at each moment of the evaluation (Pineau et al., 2009).
50 Although no standard definition of the dominant attribute exists, most recent studies define dominance
51 as the “ability of sensory attributes to catch assessors’ attention” (Di Monaco, Su, Masi & Cavella,
52 2014). TDS focuses only on the dominant attribute, not other sensory characteristics that are
53 simultaneously perceived while consuming a product. This could lead to a relevant loss of sensory
54 information when dealing with complex products that require simultaneous evaluation of multiple
55 sensory modalities (Ares & Jaeger, 2015). In TDS data, competitive effects of attributes and modalities
56 may be linked to enhanced dumping or dithering (Varela et al., 2018). To overcome these problems,
57 variations of TDS have been proposed, such as TDS by modality (Agudelo, Varela, & Fiszman, 2015;
58 Nguyen, Næs, & Varela, 2018) and dual TDS (Schlich, 2017).

59 TCATA proposes a different type of multi-attribute temporal evaluation, in which assessors are
60 asked to identify all the sensory characteristics that describe products at each moment of the evaluation
61 (Castura et al., 2016). This methodology can be regarded as an extension of (static) check-all-that-apply
62 (CATA) questions, which have become one of the most popular methods for sensory characterisation
63 with consumers (Ares & Jaeger, 2015). In TCATA, assessors are allowed to select all the attributes that
64 are perceived simultaneously during product consumption and are asked to uncheck sensory attributes
65 when they are no longer applicable (Castura et al., 2016). A potential problem of TCATA lies in the
66 complexity of the task of selecting and unselecting attributes during the evaluation period; a variant of
67 the method, called TCATA Fading, attempts to simplify the task by having attributes return to an
68 unselected state over a predetermined time period, which frees assessors from needing to deselect
69 attributes manually (Ares et al., 2016).

70 TDS and TCATA are conceptually different and, therefore, they are expected to differ in the
71 information they provide about the dynamics of the sensory characteristics of products. Information on
72 the similarities and differences between these methodologies can help practitioners to select the
73 methodology that best suits for a particular application. TDS and TCATA have been compared in several
74 studies which have shown that TCATA may give better discrimination or provide more detailed
75 information about how the sensory characteristics of products evolve over time (Ares et al., 2015;
76 Esmerino et al., 2017; Nguyen et al., 2018). In general, both TDS and TCATA identify the most relevant
77 changes in the sensory characteristics of products during consumption. However, in previous studies
78 TCATA has shown better discrimination between samples. In addition, significant differences among
79 samples were found for a larger number of attributes in TCATA than in TDS (Ares et al., 2015).
80 Typically, TCATA also gives longer periods of time with significant differences.

81 In studies comparing TDS and TCATA, data from the two methodologies have typically been
 82 analysed separately and comparisons have been done on the basis of the interpretation of the standard
 83 analyses, such as looking into significant differences, PCA trajectories, and TCATA or TDS curves.
 84 Recently (Nguyen et al., 2018) compared TDS, TCATA and TDS by modality using Canonical Variate
 85 Analysis (CVA) and MANOVA on time intervals as described in (Dinnella, Masi, Næs, & Monteleone,
 86 2013). They showed that TCATA was more discriminative and assessors were more in agreement, as
 87 compared to TDS and TDS by modality.

88 In the present work, we approach the problem of comparing the TDS and TCATA by using
 89 multivariate methods to compare the data structures directly. Many different approaches to compare two
 90 or more datasets containing measurements on the same set of samples exist. For instance, Consensus
 91 PCA (e.g., see Westerhuis, Kourti, & MacGregor, 1998), Multiple Factor Analysis (MFA; Abdi,
 92 Williams, & Valentin, 2013; Escofier & Pagès, 1994) and Canonical Correlation Analysis (CCA;
 93 Hotelling, 1936; Mardia, Kent, & Bibby, 1979). In this work we are especially interested in finding
 94 common and distinct parts in the multivariate structures of TDS and TCATA and have used the method
 95 called PCA-GCA first described in Smilde et al. (2017). This method consists of doing data reduction
 96 of single blocks by PCA first, and then using canonical correlation analysis (CCA) to find common
 97 components. The method is described in more details in section 2.3.

98 The aims of the present study are to compare TDS and TCATA using PCA-GCA in order to investigate
 99 whether the multivariate structures can give improved insight into differences observed for TDS and
 100 TCATA, and to introduce common and distinct component analyses as a tool for the sensory and
 101 consumer science field. The concept of separating common and distinct components from multiple
 102 datasets for the same set of samples has received little attention in sensory and consumer science. We
 103 expect that analysing data with respect to common and distinct components can bring a broader
 104 understanding of the relationships between interconnected data sets (e.g. chemical, sensory and
 105 consumer data for the same set of samples), or for joint analysis of several types of consumer responses.
 106 The common and distinct analysis by PCA-GCA is used to compare TDS and TCATA evaluations
 107 performed by a trained panel on yoghurt, cheese and bread samples. The results for the yoghurt data
 108 were presented at Sensometrics 2018 (Montevideo, Uruguay) and are presented with other purposes in
 109 (Nguyen et al., 2018). The cheese data have not been published before, whereas the bread data example
 110 was discussed by Varela et al. (2018).

111 2 Background

112 2.1 Data structures investigated

113 The data structures obtained from TDS and TCATA are similar in nature but with some obvious
 114 differences. In TDS (Pineau et al., 2003; Pineau et al., 2009) assessors are asked to select one attribute,
 115 the dominant one, from a list, at each moment. In TCATA (Castura et al., 2016), they are asked to select
 116 the attributes that apply to describe a focal product at each moment in time (also from a list) and can
 117 select several attributes that are applicable. For both methods, the data for each assessor can be
 118 represented as a series of 0's and 1's for each point in time, where 1 indicates selection and 0 indicates
 119 non-selection of an attribute. More precisely, with J pre-specified attributes the data for each assessor j
 120 and sample i can be represented as a matrix of 0's and 1's of dimension $J \times T$ where T represents the time
 121 points. For TDS, there will be only one 1 in each column since only one attribute can be dominant
 122 attribute at a given time, whereas for TCATA more than one of the attributes can have a value of 1.

123 Combining all samples for one assessor gives a three-way data structure (of dimension $N \times J \times T$),
 124 whereas putting all assessors together provides a four-way data structure. In this paper we will focus
 125 on the aggregated data. More specifically, for each sample the dominance rates (TDS) and the citation
 126 rates (TCATA) were computed as the average for each attribute for each time point. This leads to a
 127 three-way data table of dominance/citation rates (samples*attribute*time). Note that the sum of

128 TCATA attribute citation rates (for a product at each time point) can be higher than one since several
129 attributes can be co-selected. Data were time standardized according to Lenfant et al (2009) using the
130 R-package tempR (Castura, 2018). For multivariate analyses the three-way data is unfolded in such a
131 way that the rows represent sample*time and columns represent attributes. These vertically unfolded
132 matrices are mean centred prior to analyses. Data were also smoothed prior to the analyses.

133 2.2 Time dependent similarity between TDS and TCATA

134 The time-dependent similarity between the data arising from these two methods are investigated by
135 computing the Pearson correlation and the Euclidean distances between the data vectors obtained for
136 each time point. These vectors have one entry for each sample*attribute combination. Since the range
137 of the data vectors from TDS and TCATA differ with a maximum of one for TDS and higher for
138 TCATA, the vectors were scaled by dividing with the maximum value for each timepoint, as all
139 timepoints include at least one zero for one or more attribute*sample combinations, this make sure that
140 the data vectors from the different methods have the same range after scaling. To account for differences
141 in the number of samples and attributes, distances were normalized by dividing by the square root of
142 number of observations for each time point (number of samples x number of attributes). Plots of time
143 versus distances and correlations were applied to investigate *when* in the evaluation period the methods
144 are more or less similar. Similar patterns were identified for both the distance and correlation
145 approaches, and the result section focuses on the distance approach.

146 2.3 Analyzing multiblock data by common and distinct components

147 In food science and related fields, it is becoming more usual to have several data sets describing the
148 same set of samples. In the present paper, only two such sets (TDS and TCATA) are considered; whereas
149 in other cases there may be more datasets to describe the products: the experimental design, descriptive
150 sensory data and chemical data, or different consumer responses to the same products: liking, intake,
151 emotions elicited and so forth. For researchers, it is of great value to better understand the relationships
152 between different data sets related to the same set of samples. One approach for analyzing multiblock
153 data sets, is to identify common and unique variation for each block. The idea behind this approach is
154 that the observed data for each block can be decomposed into *common* and *distinct* components, each
155 of which contribute to the observed variability. Conceptually, the common components describe
156 variations arising from the same underlying phenomena, but that is manifested by different
157 measurements (i.e. data blocks), whereas the distinct components are related to phenomena only “seen”
158 by single data blocks. Smilde et al. (2017) discuss and compare methods for identifying common and
159 distinct components in a common mathematical framework. The performance of the different methods
160 is further discussed by Måge, Smilde, & Kloet (2018). In this work the method named PCA-GCA, which
161 will be described below, was chosen for analyzing common and distinct components in TDS and
162 TCATA data.

163 2.3.1 Separating common and distinct components: PCA-GCA

164 The overall procedure of PCA-GCA is illustrated in Figure 1. In the first step, each data block (here
165 TDS and TCATA) is decomposed by PCA. Then canonical correlation analysis (CCA; Hotelling, 1936;
166 Mardia et al., 1979) is applied to find the common components between the datasets. Next, the common
167 information is removed by orthogonalization. Finally, PCA is applied on the remaining part to structure
168 the remaining information labelled as unique. For the general case with more than two blocks,
169 generalized canonical correlation analysis (GCA; Carroll, 1968; Kettenring, 1971) is applied instead of
170 CCA. Since the methodology has been developed and named for the multiset-data case, it is here referred
171 to as PCA-GCA although CCA is applied since we work with only two blocks (TDS and TCATA).
172 Similar approaches have also been applied for regression with multiple blocks of independent variables
173 (Måge, Mevik, & Næs, 2008; Måge, Menichelli, & Næs, 2012).

174 2.3.2 Canonical correlation analysis (CCA)

175 Canonical correlation analysis can be defined as finding the linear combinations of \mathbf{X} and \mathbf{Y} with the
 176 maximum correlation. These linear combinations are called canonical variates and represent the
 177 common information in the two data sets. First the component with the largest correlation is found, after
 178 that new components are extracted using the same criterion under the restriction that the components
 179 are uncorrelated.

180 In more detail, with two blocks \mathbf{X} and \mathbf{Y} , the canonical variates are computed as linear combinations of
 181 variables in \mathbf{X} and \mathbf{Y} such that the correlation between $\mathbf{u}=\mathbf{a}'\mathbf{X}$ and $\mathbf{v}=\mathbf{b}'\mathbf{Y}$ is maximized. The next variate
 182 is obtained using the same criterion, but under the restriction of orthogonality. The central results of
 183 CCA are the canonical correlations, the canonical coefficients (\mathbf{a} , \mathbf{b}) (loadings), and the canonical
 184 variates (\mathbf{u} , \mathbf{v}) (scores). Bold letters indicate vectors.

185 Like all other correlation-based methods, CCA is sensitive to noise and overfitting. When the number
 186 of variables exceeds the number of observations (or variables are highly multi-collinear), a data
 187 compression (using for instance PCA) is needed before the canonical variates are calculated to avoid
 188 overfitting. It should be emphasized that the loadings or the coefficients of the canonical variates are not
 189 orthogonal to each other as in PCA.

190 2.3.3 Common and distinct components

191 In PCA-GCA (Smilde et al., 2017) the canonical variates with large enough correlation and which
 192 explain a considerable part of the variation, represent the variation that is common between the two
 193 datasets and will in the following be referred to as the *common components*.

194 The common variation can be removed from the data by orthogonalization with respect to the common
 195 components. The idea is that what is left after the common part is removed represents unique information
 196 for each data set (unique signal plus noise). The orthogonalization can be done in two different ways,
 197 either by orthogonalizing \mathbf{X} and \mathbf{Y} with respect to the common scores (\mathbf{C}_A), or with respect to the
 198 canonical variates for the respective blocks (\mathbf{U}_A and \mathbf{V}_A). The latter approach is more natural since the
 199 common scores are not in the space defined by \mathbf{X} and \mathbf{Y} (Langsrud, Jorgensen, Ofstad, & Næs, 2007)
 200 and is therefore applied here. This means that \mathbf{X} is orthogonalized with respect to the canonical variates
 201 obtained from \mathbf{X} , and that the same is done for \mathbf{Y} . This means that with this method we identify two
 202 separate subspaces that are *as similar as possible*. In the case of A common components, the parts of \mathbf{X}
 203 and \mathbf{Y} that are orthogonal to the common part, can be computed as

$$204 \quad \mathbf{X}_A^{\text{ort}} = \mathbf{X} - \mathbf{U}_A (\mathbf{U}_A^t \mathbf{U}_A)^{-1} \mathbf{U}_A^t \mathbf{X} \quad (2)$$

$$205 \quad \mathbf{Y}_A^{\text{ort}} = \mathbf{Y} - \mathbf{V}_A (\mathbf{V}_A^t \mathbf{V}_A)^{-1} \mathbf{V}_A^t \mathbf{Y}$$

206 After orthogonalization, the *distinct components* are obtained by PCA on \mathbf{X}^{ort} and \mathbf{Y}^{ort} . Differences
 207 between TDS and TCATA can then be investigated studying ordinary PCA plots for the unique parts,
 208 whereas the similarities are expressed as the common part, given by the canonical variates. Note that
 209 distinct components for one block are orthogonal to the common components of the same block, but not
 210 necessarily to common or distinct components from the other block.

211 2.3.4 Interpreting and selecting the number of components

212 Both common and distinct components can be interpreted and investigated by looking at scores and
 213 loadings plots in the same way as for PCA. The canonical scores (\mathbf{U} and \mathbf{V}) can be studied separately
 214 for each block, or as common scores estimated as the average of \mathbf{U} and \mathbf{V} for each component identified.
 215 Score plots for two components at a time can be obtained by plotting the scores in two-dimensional
 216 scatter plots. Each point represents one sample*time combination, and the line connecting the scores
 217 represent the time trajectory for how the samples evolve during the evaluation period. An alternative to

218 the two-dimensional score plots with trajectories is to fold the scores into a three-way structure (samples,
219 component, and time), and then plot scores versus time for one component at a time.

220 The common components can be interpreted by looking at scatter plots of the corresponding canonical
221 coefficients **a** and **b**. For distinct components, interpretation can be done using scatter plots of scores
222 and loadings from the PCA. Canonical coefficients for the common part will be investigated by
223 correlation loading plots based on correlations between the original variables (for **X** and **Y**) and the
224 corresponding canonical covariates (**U** and **V**). To enhance interpretation of the similarities and
225 differences between TDS data and TCATA data, the correlation loadings for the common components
226 are plotted together (see for instance Figure 6).

227 The number of components to keep for the initial PCA of each block is not very crucial, as long as
228 enough components are kept for further analysis. When more components are kept in PCA, the canonical
229 correlations tend to be higher. This is natural since canonical correlation analysis only focuses on
230 correlation and with more components there will be more variability to search from. In this paper we
231 decided to focus on components which together explain 90% of the variation. This is large enough for
232 capturing the majority of the variability and small enough to avoid bringing in too much of the noise. It
233 is unlikely that the last 10% of the variability in this type of quite noisy data will contribute in any useful
234 way to interpretation.

235 A canonical variate with a reasonably large correlation, but with a small explained variance may be
236 considered of little interest for interpretation. Therefore, as a general rule only components with both
237 high canonical correlation and explained variance should be considered to be common components.
238 Typically, one would want the required common components to explain at least 10% of the variance in
239 the data and to have canonical correlations of at least 0.9. Since this study has an explorative character,
240 other choices were also tested and commented on in the case studies below. Although the terminology
241 distinguishes between common and distinct components, it is important to emphasise that in practice it
242 is impossible to find components describing only common or only unique variability. Therefore, this
243 type of methodology should always be used as done here together with interpretations and testing of
244 alternative choices of number of components.

245 In this work the main aim was to study differences between TDS and TCATA, therefore different
246 combinations of common and unique components were investigated, and the number of components
247 reported were selected to highlight differences between the methods.

248 3 Material and methods

249 3.1 Panel

250 The sensory panel at Nofima has six years of experience of using temporal method as TDS and TI and
251 one-year experience with TCATA, with a range of different food products including liquids, solids and
252 semi-solids. The ten assessors were selected and trained according to recommendations in (ISO-8586,
253 2012) and are regularly trained, tested and monitored for their performance. Tests were performed in a
254 sensory laboratory designed according to guidelines in (ISO-8589, 1988) with separate booths and
255 electronic registration of data, EyeQuestion Software (Logic8 BV, Netherlands).

256 3.2 Case studies

257 TDS and TCATA were performed by the trained panel on three different cases with the products
258 yoghurt, cheese and bread. An overview of the samples for each of the cases studies are given in Table
259 1.

260 3.2.1 Yoghurt

261 The data were taken from a previous study (Nguyen et al., 2018) and were presented at Sensometrics
262 2018 (Montevideo, Uruguay). In the original study, eight yoghurt samples were made based on a 2^3

263 factorial design, with factors texture (thin-Thick), granola addition (flour-Flakes), and flavour (optimal-
264 low). Samples were evaluated by TDS, TDS by modality, and TCATA. In the present paper we use only
265 the TDS and TCATA data. For more details of the study, refer to (Nguyen et al., 2018). The design and
266 the labels used for the different products are shown in Table 1.

267 Attributes used for both tests were Acidic, Bitter, Cloying, Dry, Gritty, Sandy, Sweet, Thick, Thin, and
268 Vanilla (J=10).

269 3.2.2 Cheese

270 Six different cheese products were bought at a local store the day before analysis. The cheese products
271 were cut into pieces measuring 1x1x2 cm and put into a 3-digit marked plastic container with a lid.
272 Samples were served at room temperature.

273 The attributes included in cheese temporal evaluation were Rubber, Grainy, Nutty, Juicy, Acidic, Sticky,
274 Soft, Sweet, Salt and Umami (J=10).

275 3.2.3 Bread

276 Data were taken from a previous study where results were only discussed qualitatively (Varela et al.,
277 2018). Seven different bread products were bought and sliced early in the morning in a local store, put
278 into plastic bags, and stored at room temperature. Immediately before each session, the bread samples
279 were cut into circles with a diameter of 35 mm and put directly into a plastic container marked with a 3-
280 digit code and covered with a lid.

281 The attributes included in bread temporal evaluation were Soft, Chew resistance, Coarse, Doughy, Juicy,
282 Sweet, Acidic, Salt, and Bitter (J=9).

283 3.3 Experimental procedure

284 Attribute lists were developed in previous sessions for the purpose of (static) sensory quantitative
285 descriptive analysis (denoted QDA). From those lists, the panel selected the attributes that were relevant
286 for the temporal sensory description of the samples in a preliminary session in which they tasted two
287 different samples selected by the panel leader. The assessors developed a list of attributes, including
288 taste/flavour and texture, which was used both for TDS and TCATA tests. For each case study, two pre-
289 tests were run prior to the evaluations, as described below for each product category.

290 In both tests, attributes were presented in a circular layout on the computer screen. Assessors were
291 instructed to put the sample in their mouths and click the “Start” button simultaneously. Then, they
292 performed the TDS or TCATA test as instructed. The evaluation ended when they clicked the “Stop”
293 button at the time they were ready for swallowing.

294 For both TDS and TCATA, samples were served following a balanced rotation order, fully randomized
295 over assessor, product and replicate.

296 For the formal assessment, for both TDS and TCATA, products were evaluated in three replicates for
297 each assessor, with a compulsory 1-minute break between each sample and a 10-minute break between
298 every four samples tasted.

299 3.3.1 TDS

300 For the TDS evaluation, the assessors were instructed to put the whole sample into the mouth (bread or
301 cheese standardized piece, or a spoonful of yoghurt), and evaluate the most dominant attribute of the
302 sample at each time until the time for swallowing. Dominance was defined as the sensation that caught
303 their attention at a given time, not necessarily the most intense (ISO-13299(E), 2016). They were free
304 to choose as dominant the same attribute for the same sample as often as they deemed necessary.

305 3.3.2 TCATA

306 For the TCATA evaluation assessors were instructed to put the whole sample into the mouth (bread or
307 cheese standardized piece, or a spoonful of yoghurt), and check and uncheck all the terms from the list
308 that applied to describe the sensory profile of the sample at each time of the evaluation. They were free
309 to choose the same attribute for the same sample as often as they deemed necessary.

310 3.4 Data analyses

311 Each data set was first standardized to 100 standardized time units. Next, attribute dominance rates
312 (TDS) and attribute citation rates (TCATA) were computed and smoothed. Pre-processing steps were
313 performed using the tempR package in R (Castura, 2018).

314 The time-dependent correlation and distances between the methods were computed as described in
315 section 2.2, before the common and distinct component analysis were performed in Matlab (Matlab,
316 R2017b) using the toolbox PCAGCA which can be downloaded from
317 (<https://nofimamodeling.org/software-downloads-list>). Readers not using Matlab can easily implement
318 the procedure by combining canonical correlation analysis (CCA), principal component analysis (PCA)
319 and orthogonalization (Equation 2).

320 The number of common components were selected by looking at the canonical correlation and the
321 explained variance. A general rule is that the canonical correlation should be high, and the canonical
322 covariates should explain a substantial amount of variation (at least 10%) for common components to
323 be of interest. As for all types of multivariate analysis, the model selection (number of components) is
324 not always an easy task. The number of components is discussed separately for each of the case studies.

325 Stability of solutions from multivariate analyses should in principle be validated. Typical candidates for
326 this are cross-validation and the bootstrap, however, due to the low number of samples and assessors
327 none of these techniques are really suitable here. Instead, solutions from different sets of replicates were
328 compared. More specifically, PCA-GCA was applied for all possible combinations of replicate pairs
329 from TDS and TCATA (nine different combinations). Note that stability of single replicates will be
330 lower than averages, so results will always be on the very conservative side.

331 To assess the stability of the components, for each data set the Tucker's congruency coefficient
332 (Lorenzo-Seva, & ten Berge, J, 2006) was computed between the estimated components for all pairwise
333 comparisons for each of the case studies. For each case study, stability was assessed for two different
334 sets of models. For all models PCA with six components was applied in the first step, then stability of
335 common components was first investigated by extracting five common components. Next, stability for
336 both common and distinct components for the models selected for each case was investigated. This gives
337 insight into the identified distinct components for the selected models (the common components will be
338 the same). For each set of models, the percentage of comparisons where the congruency coefficient
339 exceeded 0.85 was computed for each component.

340 4 Results and discussion

341 For the yoghurt we refer to (Nguyen et al., 2018), for a detailed description of results obtained for TDS
342 and TCATA. For the two other sets, overviews of results are presented in the appendices. Here we only
343 focus on results from the common – distinct part analyses described in section 2.3.

344 4.1 Overall comparison

345 An overall comparison of the methods was performed by a visual comparison of PCA plots of the
346 unfolded data from TDS and TCATA for each of the case studies. In general, the trajectories were
347 similar and could be interpreted in the same way, but with some differences. In the PCA plots for the
348 bread case study (Figure 2), the TDS trajectories are more entangled than the TCATA trajectories. In
349 the beginning of the evaluation the samples were relatively well separated by both methods. For most

350 samples the TCATA trajectories remained separated throughout the evaluation, whereas for TDS the
351 trajectories ended up in a bundle towards the end (Figure 2). The relative entanglement of TDS
352 trajectories vis-à-vis the TCATA trajectories was most pronounced in the bread case study, but also
353 observed in data from the other case studies (not shown). For the yoghurts and the cheeses, the two or
354 three first components had similar overall patterns. These two datasets were also less complex than the
355 bread study, as some samples were clearly separated from the others also along the first component.
356 Moreover, a larger part of the variation was explained with fewer components for TCATA data than for
357 TDS data (Figure 3). This will be discussed further for each case study below.

358 PCA-GCA was also tested on raw data without smoothing (not shown). Since the raw data are much
359 more complex, these analyses provided a larger number of components which were more difficult to
360 interpret. With smoothing, a large part of the noise is removed, and the analysis can focus more on the
361 information and real structure in the data. The overall impression of similarities and differences between
362 the data arising from TDS and TCATA methods were similar for the unsmoothed data as for the
363 smoothed data.

364 4.2 Similarity over time

365 Figure 4 shows normalized distances between the two data vectors obtained for each method (TDS,
366 TCATA) when looking at single time points. For all three cases, the distance is smallest in the early
367 phase (from $t=0$ to $t=20$), then increases between approximately $t=20$ and $t=40$. The increase is clearly
368 slower for bread than the other two cases, whereas the distance between TDS and TCATA in early phase
369 is higher for the yoghurt than the other datasets. The time-dependent correlations showed a similar
370 pattern with a drop in correlations between $t=20$ and $t=40$ (not shown).

371 The curves in Figure 4 indicate that TDS and TCATA provide very similar results in the early phase,
372 which is not surprising as the PCA plots (Figure 2) indicated that samples are better separated in the
373 early phase of the evaluation. A possible explanation for good early separation of samples is that textures
374 in the bolus formation tend to be more similar between products within the same product category as
375 compared to intact samples (Peyron et al., 2011). The point where TDS and TCATA start to become
376 more different may be close to the point where the bolus starts to form. Bolus formation has a high inter-
377 individual variability (Panouille, Saint-Eve, Deleris, Le Bleis, & Souchon, 2014; Yven et al., 2012),
378 which may be differently reflected in TDS and TCATA. TCATA has been shown to reflect a more
379 complete sample description than TDS (Nguyen et al., 2018; Ares et al., 2015), so would be assumed to
380 provide a more complete characterization of the dynamic transition from an intact product to a bolus.
381 There may also be variations in when assessors add/remove applicable attributes in TCATA (Meyners
382 & Castura, 2018).

383 4.3 How many common components?

384 In each of the case studies, the first six principal components (PCs) were used for input in the common-
385 distinct analysis based on canonical correlation analysis. These components accounted for at least 90%
386 of the variance in the data (Figure 3a). Typically, more components were needed for TDS than TCATA
387 to account for 90% of the variance (Figure 3a). We have, however, chosen to use the same number of
388 components for both methods.

389 The canonical correlation coefficients are shown in Figure 3a, whereas Figure 3b-d show the explained
390 variance for PCA, and for the common components when computing up to five common components in
391 each of the three examples. The datasets differ in how much of the variation was described by the
392 common components. The common components explained almost as much of the variation as the PCA
393 components, but with some differences between TDS and TCATA, and also between the different cases,
394 which will be discussed below.

395 Selecting the number of common components can be a difficult task. As the main focus here is to better
396 understand the differences between TDS and TCATA, different combinations of common and distinct

397 components were investigated by looking at scores for pairs of components (trajectories) or as functions
398 over time (see section 2.3.4). For some combinations it was observed that the distinct components had
399 similar interpretations for both TDS and TCATA in some of the examples. For these cases, more
400 components were selected as common although the canonical correlations were not that high. This
401 strategy was selected since the main aim was to study differences between the two methodologies. This
402 illustrates that the concept of common and distinct components is not black and white, such that
403 components are often neither completely common, nor completely distinct, but something in between.
404 The words *common* and *distinct*, are used to label the part of the variation (common or unique) they
405 mostly describe.

406 Below the three case studies are discussed separately. Since the focus of this work is to find out if there
407 is unique information in either TDS or TCATA, we interpret more components than what is usually
408 done for this type of data.

409 4.4 Detailed description of the case studies

410 Prescripts D- and A- are used to denote dominant (TDS) and applicable (TCATA) attributes,
411 respectively; attributes mentioned without prescript are similar for both methods.

412 4.4.1 Yoghurt

413 The data from the yoghurt study are summarized in supplementary Figure A1.1. For more info and
414 discussion on the results, please refer to (Nguyen et al., 2018). Figure 4a shows a steady decrease in the
415 canonical correlation from one to five components, without a clear breaking point. The canonical
416 correlations were the lowest among the three case studies.

417 When looking at PCA results, the explained variance after three components was clearly higher for
418 TCATA than TDS (Figure 3b). Common components 1-3 explained almost as much variation as for the
419 separate PCA models, indicating little extra information in any of the datasets. For TCATA there was a
420 clear breaking point after three components, fitting with three experimental factors, whereas for TDS no
421 such break point existed. Due to this breaking point, we focused on a solution with three common
422 components.

423 *Common components*

424 The three first common components gave similar trajectories as the separate PCAs which were discussed
425 in (Nguyen et al., 2018) The scores for common component 1 (C_1) and common component 3 (C_3) are
426 given in Figure 5a (TDS) and 5b (TCATA). For both methods, these components gave four classes of
427 trajectories related to thickness of yoghurt (Thick-Thin) and the type of fiber added (Flour-Flakes).
428 Samples were, however, better separated for TCATA than TDS, in particular with respect to low-optimal
429 flavour in C_3 for yoghurts with flour (right side of Figure 5 b). Common component 2 (C_2) was related
430 to the overall time development and did not separate the yoghurt samples for either of the methods.

431 Figure 5c) shows the correlation loadings for C_1 and C_3 from TDS and TCATA data (see section 2.4).
432 For both methods C_1 was related to Sandy (positive side) and Gritty (negative side). C_3 was related to
433 Thin (positive direction) and Thick (negative direction). In general, the attributes from TDS and TCATA
434 had similar positions. The largest differences were observed for Acidic and Vanilla which may explain
435 the better separation with TCATA. The dominance rate of Vanilla was quite low in TDS and always
436 below the significance level, whereas in TCATA samples with higher Vanilla intensity could be well
437 differentiated from the low-flavour samples (Supplementary Figure A1.1). Also, for Sweet the
438 dominance rate was low in TDS, although a difference between optimal and low flavour yoghurts can
439 be seen during the 20 first time units. With TCATA on the other hand, citation frequency is higher for
440 the optimal flavour yoghurts throughout the whole evaluation. In this case study, TCATA elucidated
441 differences between optimal and low-flavour samples better than TDS. For more detailed info on the
442 complete sensory profiles, please refer to (Nguyen et al., 2018).

443 *Distinct components*

444 The trajectories for C_2 and distinct component 1 (D_1) (after three common components were extracted)
 445 are shown for TDS and TCATA in Figure 6 a and b, respectively. The D_1 from TCATA separated low-
 446 optimal flavour, whereas for TDS this distinct component was difficult to interpret since the trajectories
 447 in this plot are completely intertwined. Figure 6c shows the correlation loadings for TCATA C_2 and D_1 ,
 448 where both Sweet and Vanilla loads on D_1 , with interpretation aligned with observations in the previous
 449 section regarding these two attributes.

450 *4.4.2 Cheese*

451 The data from the cheese study are summarized in Supplementary Fig. A1.2. There was a clear drop in
 452 the canonical correlation after two components which are close to 1 (Figure 3a). It is therefore natural
 453 to focus on two common components for this data set. Among the three case studies, the canonical
 454 correlations are highest for cheese for two first components, but lowest after five components.

455 From Figure 3c it is evident that TCATA was better explained with fewer components than TDS. For
 456 TCATA, the amount of variation explained by the common components was almost the same as for the
 457 principal components, whereas there was some additional variability in TDS not explained by the
 458 common components.

459 *Common components*

460 TDS and TCATA trajectories for the two first common components (C_1 and C_2) were quite similar
 461 (Figure 7a and b). The C_1 separated semi-hard firm cheeses (samples JA and KO) from the rest. The
 462 other cheeses were separated by C_2 in the first half of the evaluation, then around the mid-point of the
 463 evaluation trajectories cross each other, and in the second half they are better separated by C_1 . The
 464 separation is slightly better with TCATA than TDS.

465 Attributes loading on C_1 were Nutty, Rubber, Grainy and Sweet (Figure 7c). These attributes were cited
 466 more frequently for JA and KO, but infrequently for the other cheeses (Supplementary Fig. A1.2). In
 467 addition, D-Juicy and D-Acidic loads on the positive side for the TDS data, whereas A-Salt for TCATA
 468 data is correlated with A-Umami on the negative side of C_2 (Figure 7c). The C_2 describes a contrast
 469 between Soft (start of evaluation) and Sticky/Umami (end of evaluation).

470 *Distinct components*

471 The differences between TDS and TCATA become more apparent when considering trajectories for C_2
 472 and the first distinct components (D_{11} for TDS and D_{21} for TCATA) as shown in Figure 8a and b for
 473 TDS and TCATA respectively. Based on TDS data, the cheeses KO and JA show no dynamics related
 474 to these two components (trajectories are only in the middle of the plot and very short). For TCATA
 475 data on the other hand, the component D_{21} is clearly related to dynamical changes in these two cheeses,
 476 and trajectories for KO and JA are near vertical. The trajectories are generally better separated in Figure
 477 8b than a; although the D_{11} explains more of the variability in TDS (19.0%) than D_{21} does for TCATA
 478 (9.1%). The pair NR/GR was not well separated by any of the methods, not even when looking at later
 479 components.

480 The distinct components D_{11} and D_{21} are both related to Sweet, Juicy and Acidic, however D-Juicy and
 481 D-Acidic also contribute to C_2 , hence these attributes are located differently in Figure 8c and d. With
 482 TDS, D-Soft loads on the negative direction of D_{11} , whereas remaining attributes are in the centre of
 483 Figure 8c. With TCATA data the distinct component contrasts A-Nutty and A-Grainy (together with
 484 Sweet, Juicy and Acidic), and A-Rubber. The almost vertical trajectories for KO and JA in Figure 7b
 485 are related to temporal changes in these attributes.

486 *4.4.3 Bread*

487 The data from the bread study are summarized in Supplementary Fig. A1.3. Canonical correlations were
 488 high (>0.7) for up to five common components (Figure 3a), and there was no clear breaking point.

489 *Comparing TDS and TCATA for the full evaluation period*

490 The explained variances for separate PCAs and the common components (Figure 3d) showed a different
 491 pattern than for the two previous cases. Both PCA explained higher variances (dotted lines, Figure 3d)
 492 than did the curves for the common components (solid lines, Figure 3d), in particular when looking at
 493 explained variance for two and three common components. Thus, there was additional variation in each
 494 of the data sets which could represent unique information. Distinct components were, however, difficult
 495 to identify as the so-called distinct components from TDS and TCATA could be interpreted in the same
 496 way, and hence did not represent unique information after all.

497 There were, however, several indications that TDS and TCATA differed more in the later part of the
 498 evaluation period. In the trajectory plots from the separate PCA models (Figure 2), the TDS trajectories
 499 (Figure 2a) became intertwined around the mid-point, whereas the TCATA plot (Figure 2b) trajectories
 500 were better separated throughout the whole period. Also, when looking at the detailed profiles for the
 501 bread (Supplementary Fig. A1.3), Coarse, Softness and in a lesser extent Chew resistance seemed to
 502 drive the temporal perception in the beginning of the mastication (before $t=50$). Towards the end of the
 503 evaluation, when the samples had reached a bolus state, TDS becomes more variable. The complexity
 504 associated with choosing only one attribute, as well as individual differences in bolus formation (Yven
 505 et al., 2012) may explain why the two methods showed fewer common characteristics at this stage of
 506 the evaluation. Another possible explanation is that assessors may forget to unselect attributes in
 507 TCATA (Ares et al., 2015; Meyners & Castura, 2018).

508 To get better insight into whether TDS and TCATA provided different information about the bread
 509 samples, the analyses on common and distinct components were repeated for data after $t=50$, coinciding
 510 approximately with where the largest differences between methods were observed.

511 *Comparing TDS and TCATA for the second half of the evaluation period*

512 The canonical correlations for the reduced bread data ($t>50$) are shown in Figure 9, with a clear breaking
 513 point after three components. Explained variances for the three first common components were larger
 514 than 20% (33.7%, 22.5% and 25.2% for TDS; 34.8%, 25.4% and 21.3% for TCATA). Focus is therefore
 515 on a model with three common components. Again, interpretation is important when selecting the
 516 number of components and here the focus was on highlighting differences between the methods.

517 Trajectories for the two first common components are shown in Figure 10a and b, with the corresponding
 518 correlation loadings in Figure 10c. Similar to the other examples, the trajectories were more entangled
 519 for TDS than TCATA. C_1 was dominated by Bitter (negative side) and Juicy, Soft and Acidic (positive
 520 side). The C_2 was related to texture attributes with Coarse (positive side), and Doughy and Salt (negative
 521 side). Attributes from TDS and TCATA were mostly located in the same area of the plot, but with some
 522 differences for Doughy, which for TDS was located more on the left side compared to TCATA.

523 The trajectories for the two first distinct components are shown in Figure 11a and b for TDS and TCATA
 524 respectively. It is clear that the separation of samples was better for TCATA than TDS, although not all
 525 samples could be discriminated. For TCATA (Figure 11 c), D_1 was related to Sweet and Salt, whereas
 526 D_2 , which only explained 7% of the variability, was related to Chew resistance.

527 4.5 Discussion of all case studies

528 The present work aimed at exploring the common and unique information provided by TDS and TCATA
 529 in order to provide insights to practitioners for selecting the methodology that best suits for a particular
 530 application. There were quite large differences between the samples and therefore the common
 531 components were often related to single or pairs of samples. With such large differences between
 532 samples, the methods were highly similar with respect to explain variation and interpretation of the
 533 components. This agrees with previous research comparing TDS and TCATA reporting that the methods
 534 provide similar information about the main similarities and differences among samples, particularly
 535 when marked differences exist (Ares et al., 2015). More differences are expected for situations where

536 the samples have more subtle differences, for instance when working with small improvements on
537 existing recipes in product development projects.

538 For the full data sets in the bread study, the difference between explained variation by common
539 components and PCA components on TDS and TCATA separately was larger than for the other
540 examples (Figure 3d). Nevertheless, it was difficult to extract meaningful distinct components, which
541 may indicate that for both methods there may be substantial noise in the data. When discarding data
542 from the first part of the evaluation and focusing on the period where the sample has turned into a bolus,
543 differences between the methods were clearer. In this part of mastication period the dominating attribute
544 may be more difficult to identify by TDS. The competition between texture and flavour attributes during
545 mastication (before bolus state) is perhaps larger in bread compared to the other examples as it is a solid
546 and relatively dry product.

547 The separation of common and distinct components when comparing TDS and TCATA provided some
548 interesting results. First of all, the common components explained TCATA better than TDS; which also
549 needed more components to explain the same amount of variation as for TCATA when analyzing the
550 data separately by PCA. One of the reasons of the higher complexity of TDS is more “ups and downs”
551 in the dominance curves compared to the citation rates of TCATA. The differences between the distinct
552 components for these two methodologies can occur due to the greater sensitivity of the TCATA method,
553 that TCATA assessors forget to unselect attributes, or that assessors in TDS have more uncertainty when
554 selecting the dominant attribute (Varela et al., 2018). Each of these explanations are plausible, but the
555 fact that the additional variation in TDS was difficult to interpret may indicate that assessor
556 heterogeneity with respect to conceptualization of dominance is an important factor. The better
557 discrimination ability with TCATA can be explained by a more structured variation, i.e. more variation
558 explained by fewer components.

559 Using the yoghurt data and hypothesis testing for the different attributes and time points Meyners (2018)
560 concluded that the two methods are very different. One of the main conclusions was that TCATA
561 generally gave smaller p-values than TDS, and significant differences occur more often. Moreover, the
562 duration of significant differences lasted longer with TCATA than for TDS (Meyners, 2018). The results
563 from the multivariate study conducted here, however, showed a large degree in similarity between the
564 methods. It is important to emphasise that this does not necessarily mean a contradiction of the result by
565 Meyners (2018), since both focus, hypotheses, type of results considered, and assumptions of TDS and
566 TCATA methods are different. This paper compares in particular the multivariate structures in order to
567 explore differences in overall discrimination of products. The approach of looking for common and
568 distinct components by applying PCA-GCA shows that the main structures are indeed similar. The
569 similarity in structures of multivariate data was also to be expected since several TDS and TCATA
570 comparisons have concluded that the methods provide similar descriptions, but that the unique
571 components of TCATA seem to discriminate samples better than for TDS. In our point of view, it is also
572 natural that a method which measures whether an attribute is dominant detects significant differences
573 less frequently than a method which measures whether the attribute characterizes the sample; more
574 attributes characterize the sample than are dominant, and it is natural to expect that perceptual
575 characterization will be more stable for dominance, and for longer durations.

576 4.6 Stability of the common components

577 PCA-GCA was performed for all combinations of the pairs of replicates as described in section 3.4. For
578 all case studies the explained variance for common components and PCA was similar to the results for
579 the complete data sets (not shown). When discussing stability of common components, we focus on
580 results obtained for models with five common components (see section 3.4). The stability of the distinct
581 components was generally lower than for the common components, but this is to be expected as the
582 explained variation of the distinct components are lower than for the common components.

583 Nevertheless, in the present comparisons of data from TDS and TCATA the differences between the
584 methods became more evident in these components.

585 *Yoghurt*

586 The common components extracted from TCATA were more stable than for TDS according to Tucker's
587 congruency coefficient. The congruency coefficients for the two first common components exceeded
588 0.85 in more than 50% of the comparisons for TDS and 70% for TCATA. The third component was
589 considerably less stable. This could indicate that a model with only two common components would be
590 most appropriate for this case study. However, for the model with only two common components the
591 first distinct component had very similar interpretation for both TDS and TCATA, demonstrating that
592 the transition from common to distinct variation often is gradual. When applying the model with three
593 common components, the first distinct components (Figure 6c) highlighted better the differences
594 between the methods. This shows that interpretation is important in model selection in exploratory
595 analyses. Because of this interpretational aspect, the model with three common components was
596 preferred for the yoghurt case, although the third common component was less stable than the two first.

597 *Cheese*

598 For the Cheese data, there was no clear differences between stability of common components from TDS
599 and TCATA. The stability was high for the two first common components. In contrast to the Yoghurt
600 case described above, no additional insight on differences between TDS and TCATA could be obtained
601 by extracting additional common components. Hence, for this case the stability results confirmed the
602 previous model selection.

603 *Bread*

604 For the Bread data the congruence coefficients indicated low stability of the components, reflecting a
605 higher noise level and more variation between the replicates. However, Måge et al. (2019) demonstrated
606 that PCA-GCA does not give false discoveries, i.e. extracting common components when there are none
607 in the underlying model. Thus, the lack of consistency between replicates of bread evaluations may be
608 related to a larger competition between texture and flavour attributes for bread than the other products
609 as discussed above. Based on simulation studies Måge et al. (2019) reported that PCA-GCA performed
610 well with respect to selecting the correct number of components. Problems could, however, occur for
611 noisy data when common components dominate the blocks and there is little systematic distinct
612 variation. This situation may be the case for the Bread data. The canonical correlations indicated a large
613 number of common components, in particular when analysing data from complete evaluation period.
614 Nevertheless, there was a gap in the explained variation between principal and common (canonical)
615 components, which indicated unique variability for each data block. Distinct components were,
616 however, more difficult to identify than for the other cases as the interpretation was the same for both
617 blocks also when a large number of common components were extracted.

618 4.7 Future challenges and implications

619 In the present work, the temporal data were first compressed by PCA. Another alternative would have
620 been to use correspondence analysis (CA) which has also been applied to study trajectories of temporal
621 data (Castura et al. 2016). An anonymous reviewer suggested that the blocks of data can be analysed by
622 CA, followed by decomposition into common and unique components via GCA. Such an approach could
623 be considered a topic for further research.

624 Varela et al. (2018) discussed competition between modalities rather than attributes in TDS; i.e. that
625 assessors must choose one attribute at a time which can only belong to one modality (flavour vs. texture).
626 Textural attributes will more likely be chosen when food physics dominates the oral processing
627 (beginning of the mastication or formation of the bolus at the end). Flavour attributes on the other hand
628 are more likely to be chosen during the middle of the oral processing, when saliva release and wetting
629 of the sample dominate the process. It is therefore interesting to see that it is mostly flavour attributes
630 which contribute to better separation with TCATA than TDS. Better separation of samples with TCATA

631 than TDS was in particular observed for yoghurt and bread, and in both these examples the distinct
 632 components were related to flavour attributes; Sweet and Vanilla for yoghurt (Figure 6c) and Sweet and
 633 Salt for bread (Figure 10c). In the cheese study both texture and flavour attributes differed for the distinct
 634 components (Figure 8c and d), however, there were some differences in how some of the flavour
 635 attributes loaded on the common components (Figure 7c).

636 It is clear that difference between TDS and TCATA can vary during the evaluation period since the
 637 better sample separation observed for TCATA seems to be related to the second half of the evaluation
 638 period (this is when TDS trajectories tend to become more entangled). Further investigations should
 639 therefore to a larger extent focus more on different time intervals. Temporal data have been divided into
 640 intervals in for instance Dinnella et al. (2013) and by Nguyen et al. (2018). With similar strategies as
 641 those papers, the distinct-component analyses can be performed separately for each time interval. Such
 642 data analyses can be expected to shed more light on the relationship between textural and flavour
 643 attributes for different temporal methods and how these are perceived during the mastication process.

644 5 Conclusions

645 A trained panel analysed samples from three different product categories using TDS and TCATA. The
 646 data from the two methods were analysed using PCA-GCA which is a framework for extracting common
 647 and unique information, through sequential application of PCA, canonical correlation analysis and
 648 orthogonalization. This tool was useful for highlighting and visualising differences between TDS and
 649 TCATA although some difficulties in selecting model was experienced for the bread data. The stability
 650 of the solutions was investigated by comparing replicates. The results were sufficient for a proper
 651 interpretation.

652 By use of PCA-GCA a large degree of similarity in the multivariate structure between data from TDS
 653 and TCATA was observed for all three product categories in the study. TCATA discriminated samples
 654 better than TDS both when looking at common components, and also when components which have the
 655 highest similarity between the methods (the common parts) were extracted. Differences in sample
 656 separation were mostly related to flavour attributes, this suggests that TCATA provides better separation
 657 than TDS because there is less competition between modalities than in TDS. The results support
 658 previous findings and suggest that the opportunity to select more attributes in TCATA provides more
 659 structured (less variable) data. The unique information in TDS shows more fluctuations in perception
 660 dynamics (wiggly curves). More research is needed to understand if the small fluctuations in TDS are
 661 relevant to consumer acceptance. Further comparisons of TDS and TCATA should focus on different
 662 parts of the mastication process, use samples with subtle differences or link the data to consumer
 663 acceptance data.

664 Acknowledgements

665 We would like to thank FFL: [Norwegian] Fund for Research Fees for Agricultural Products for
 666 financial support. We also thank the reviewers for their helpful comments for improving the paper and
 667 Quoc Cuong Nguyen for providing data for the yoghurt study.

764 Table 1: Overview of samples for each case study21

765

766 Figure 1: Overview of the procedure for analysing common and distinct components22

767 Figure 2: PCA trajectories for the bread data.....23

768 Figure 3: a) Canonical correlation coefficients for all three examples b-d) Explained variation
 769 for PCA and common/distinct components for TDS and TCATA. The dotted lines show the
 770 cumulative explained variance for the separate PCAs, whereas the solid lines show the
 771 cumulative explained variance for the five first common components, the sixth component is
 772 distinct. Circles are used for TDS whereas pluses are used for TCATA. Bars show the
 773 explained variance in the order as given in the legend for each subplot. a) yoghurt, b) bread
 774 d) cheese.24

775 Figure 4: Distance between TDS and TCATA for each time point in the evaluation.25

776 Figure 5: Yoghurt data, a) Trajectories for common component 1 and 3 for TDS, b).
 777 Trajectories for common component 1 and 3 for TCATA. The labels in a and b mark the
 778 starting point of the evaluation. Sample acronyms: t-f = thin-flour, t-F = thin Flakes, T-f =
 779 Thick-flour, T-F = Thick Flakes. Dashed and solid lines represent optimal and low flavour
 780 respectively c) Correlation loadings for common component 1 and 3. TCATA attributes are
 781 marked with A-, whereas TDS attributes are marked with D-. When the angle between the
 782 same attributes exceeds 30° attribute labels are in italics. Attributes outside the inner circle
 783 which mark 50% explained variance, have larger fonts.26

784 Figure 6: Yoghurt data a) Common 2 + 1 distinct TDS. b) Common 2 + 1 Distinct TCATA,
 785 Sample acronyms: t-f = thin-flour, t-F = thin Flakes, T-f = Thick-flour, T-F = Thick Flakes. c)
 786 Correlation loadings for common component 2 and the first distinct component of TCATA
 787 after extracting three common components. Attributes outside the inner circle which mark
 788 50% explained variance, have larger fonts.27

789 Figure 7: Cheese data a) Common components 1 and 2 for TDS, b) Common components 1
 790 and 2 for TCATA, c) Correlation loadings for common component 1 and 2. A- marks
 791 attributes from TCATA, D- marks attributes from TDS. When labels are in italics, the angle
 792 between A-x and D-x exceeds 30°. Larger fonts are used for attributes which have a
 793 correlation of more than 0.5 to the components shown.....28

794 Figure 8: Cheese data a) Common components 1 and 2 for TDS, b) Common components 1
 795 and 2 for TCATA, c) Correlation loadings for common component 2 and distinct component
 796 1, TDS d) Correlation loadings for common component 2 and distinct component 1, TCATA.
 797 A- marks attributes from TCATA, D- marks attributes from TDS. °. Larger fonts are used for
 798 attributes which have a correlation of more than 0.5 to the components shown.....29
